

The effect of education on teenage fertility: causal evidence for Argentina¹

María Laura Alzúa; CEDLAS-UNLP, UBA and Conicet
Cecilia Velázquez; CEDLAS-UNLP and CINVE²

Abstract

This is the first study exploring the causal effect of education on teenage fertility in Argentina. We exploit exogenous variation in education from the staggered implementation of the 1993 reform, which increased compulsory schooling from seven to ten years. We find a negative overall impact of education on teenage fertility rates, which operates through two complementing channels: a human capital effect (one additional year of schooling causes a decline of 30 births per 1,000 girls) and a weaker ‘incapacitation’ effect (a rise of one percentage point in enrollment rate reduces 3 births per 1,000 girls).

JEL Codes: I28, J13.

Keywords: Teenage fertility, Education, Instrumental variables, Compulsory schooling laws, Latin America and the Caribbean, Argentina.

¹ This paper is based on the first chapter of Cecilia Velázquez's Ph.D dissertation at Universidad Nacional de La Plata (UNLP). An earlier version was awarded with the prize “Premio ANCE 2014” delivered by Academia Nacional de Ciencias Económicas (Argentina). This work has been carried out with financial support from a Postgraduate Scholarship provided by ANII (Uruguay) and the 4th Scholarship Essay Contest organized by CEDLAS (Argentina), CIEDUR (Uruguay) and IDRC (Canada).

1. INTRODUCTION

Early motherhood represents a major challenge for policymakers in those countries committed to the Millenium Development Goals (Jiménez et al., 2011; Williamson, 2013). In particular, Latin America and the Caribbean (LAC) is the second region (following Africa) with the highest teenage fertility rate in the world, with 68 births per 1,000 women between the ages of 15 and 19 (United Nations, 2013). While in most LAC countries teenage fertility rates declined in the last decade, in Argentina rates increased sharply since 2003 as indicated in Figure 1. Data also indicate high heterogeneity across provinces: Argentina's northeast region rates almost equal those of the Sub-Saharan Africa, as it can be observed in Figure 2.

Teenage pregnancy relates to several adverse consequences on child health (Azevedo et al., 2012). These risks include low birth weight, pre-term delivery, and neonatal and infant mortality. These consequences are more severe when the mother is young (14 years of age or less). Table 1 shows such effects according to the age of the mother for Argentina.

Early childbearing also relates to adverse intra-generational socioeconomic consequences for the mothers (lower educational achievement and poorer labor market outcomes) and inter-generational negative socioeconomic consequences for the child (engagement in risky behaviors). In addition, being born to a teenage mom is associated with higher risk of a teenage birth (binding inter-generational poverty traps). Regardless of the individual costs associated with the phenomenon, teenage pregnancy has a considerable public cost: health and welfare costs, since teen mothers are more likely to participate in social programs and become dependent on social assistance income; Azevedo et al. (2012).

Education is a key determinant of fertility choices³ and may affect them through different channels. The first causal channel relies on human capital theory and understands education as an investment for the future: education raises future earnings and ultimately the opportunity cost of early childbearing (Becker, 1960 and 1981).⁴ This negative effect of female education on fertility could be stronger under positive assortative mating

³ Literature on fertility distinguishes between direct (proximate) and indirect (distal) determinants. Proximate determinants are biological and behavioral factors (marriage, contraception, abortion and postpartum infecundity) through which education and others socioeconomic, cultural and environmental 'background' variables affect fertility (Bongaarts, 1978 and 1982).

⁴ Higher earnings raise the opportunity costs of leaving the labor market to bear a child (negative 'substitution effect'); but higher earnings should be positively related to fertility because families can afford more children (positive 'income effect'). However, this income effect may be weaker if parents with higher income prefer to invest more in each child (quantity-quality tradeoff). It is expected that the substitution effect dominates the income effect, so education reduces fertility.

(Behrman and Rosenzweig, 2002).⁵ Second, education may also operate through a delay of first births during the teenage years⁶ through a pure ‘incapacitation’ or ‘incarceration’ effect: keeping teenagers in school, under adult supervision, limits their time/opportunities to engage in risky behavior like unprotected sex.⁷ Such birth postponement may also be related to the role incompatibility of enrollment in the educational system and motherhood (Black et al., 2008).

There are other causal channels by which education could affect fertility. For instance, the effect of education on women's knowledge about contraception or reproductive health (via curricula); or by teaching reasoning skills which foster knowledge after leaving school, i.e., education is associated with higher productivity in the production of health (Grossman, 1972).

Although a vast empirical literature shows a negative association between female education and early fertility (for international references, see Azevedo et al., 2012; for LAC countries, see Florez and Nuñez, 2001; for Argentina, see Figure 3), it is difficult to establish a causal relationship due to endogeneity problems. Human capital accumulation and reproductive decisions are either joint decisions, which result in a potential reverse causality problem or are both affected by unobservable factors, causing selection bias.

Some recent studies used different methodological approaches to overcome selection bias and reverse causality problems; isolating the ‘pure’ effect of education on teenage fertility. Experimental or quasi-experimental research designs exploited policies that reduce schooling costs (direct and opportunity costs) and rise enrollment (i.e. Conditional Cash Transfer programs and enrollment subsidies), differences in age-at-school-entry policies, reforms that extended the length of the school day, and reforms that extended compulsory schooling. Empirical evidence for OECD countries (Black et al., 2008; Silles, 2011; Cygan-Rehm and Maeder, 2013)⁸ and Africa (Baird

⁵ Under positive assortative mating a woman's education is causally connected to her mate's education, so that the effect of education on household permanent income is augmented through a multiplier effect.

⁶ Birth postponement may be temporary and does not necessarily affect completed fertility.

⁷ In sub-Saharan African countries there is concern about “schoolgirl pregnancy”, a term that draws attention to the risks schoolgirls face when they stay in school beyond the age of sexual maturity. Pregnancy amongst school-going adolescents has increased in sub-Saharan Africa in recent years because of the rapid expansion of girls' schooling and the steady decline in age at puberty, there are simply more African girls now in school for longer periods after they have reached puberty than there were in the past (Lloyd and Mensch, 2006).

⁸ An exception is McCrary and Royer (2011) who do not find any causal effect of education on fertility behavior for the United States. The seemingly conflicting evidence could be due to differences in the type of intervention involved. While in all studies the number of years of schooling increases, the intervention examined by McCrary and Royer (2011) affected school entrance decisions whereas Black et al. (2008), Silles (2011) and Cygan-Rehm and Maeder (2013) investigate reforms that affected school exit decisions. The latter type of intervention is likely to matter more for women who desire to have children early in life but who wish to avoid violating compulsory schooling laws. Prolonging compulsory school by one year will possibly lead such women to postpone childbearing by the same amount of time. Compared to interventions that manipulate school entry age, school exit policies are

et al., 2011; Duflo et al., 2015) supports the hypothesis that education reduces fertility among youth. However, evidence for LAC countries is mixed. On the one hand, the cross-country analysis of Alzúa et al. (2016) based on 22 LAC countries finds that education has no impact on teenage fertility for the region. On the other hand, there is evidence that education negatively affects teenage fertility for Colombia, Chile and Dominican Republic (Cortés et al., 2010 and 2016; Berthelon and Kruger, 2011; and Novella and Ripani, 2015).

This paper provides empirical evidence on the impact of education on teenage fertility for Argentina that helps shed light on the conflicting evidence for LAC. We exploit a natural experiment: an education reform (*Ley Federal de Educación*, 1993) that among several features increased compulsory schooling from seven to ten years. Although it was a national reform, its actual implementation was driven by political reasons and varied substantially across provinces (Alzúa et al., 2015). Differences in timing and degree of implementation provide a source of identification for unraveling the causal effect of education on teenage fertility using an Instrumental Variables approach. To the best of our knowledge, this is the first study exploring the case of Argentina.

We use an annual panel dataset at the birth-cohort/province level for the period 1995-2006. Results provide evidence for a positive impact of education reform on educational outcomes (*first-stage* relationship). In fact, the implementation of the reform (extensive margin) had a statistically significant and positive effect range from 0.24 to 0.27 additional years of schooling; and it also produced an increase in school enrollment rates, ranging from 2.6 to 3 percentage points. However, the reform's progress and expansion (intensive margin) showed no impact on human capital or enrollment.

We find evidence for a statistically significant negative overall impact of education on the fertility decisions of teenagers. This overall effect is found to operate through two complementing education channels: a human capital effect (one additional year of schooling reduces teenage fertility rate by roughly 26.9 to 35.5 per thousand points) and a weaker 'incapacitation' effect (a rise of one percentage point in enrollment rate reduces the teenage fertility rate by roughly 2.4 to 3.3 per thousand points). Crosta (2007) found that the 1993 education reform reduced repetition rates, this may be explaining the weak 'incapacitation' effect (similar to the case of Malawi; Grant, 2015).

therefore likely to capture not only the effect of increased human capital, but also that of the mechanical delay related to the woman's desire not to violate the law.

Although the estimated effects are very large, we should interpret the results as a local average treatment effect (LATE) for the group complying with the reform (i.e. for young people who did not leave school after seven years because of the reform). This group is not necessarily representative of the overall population.

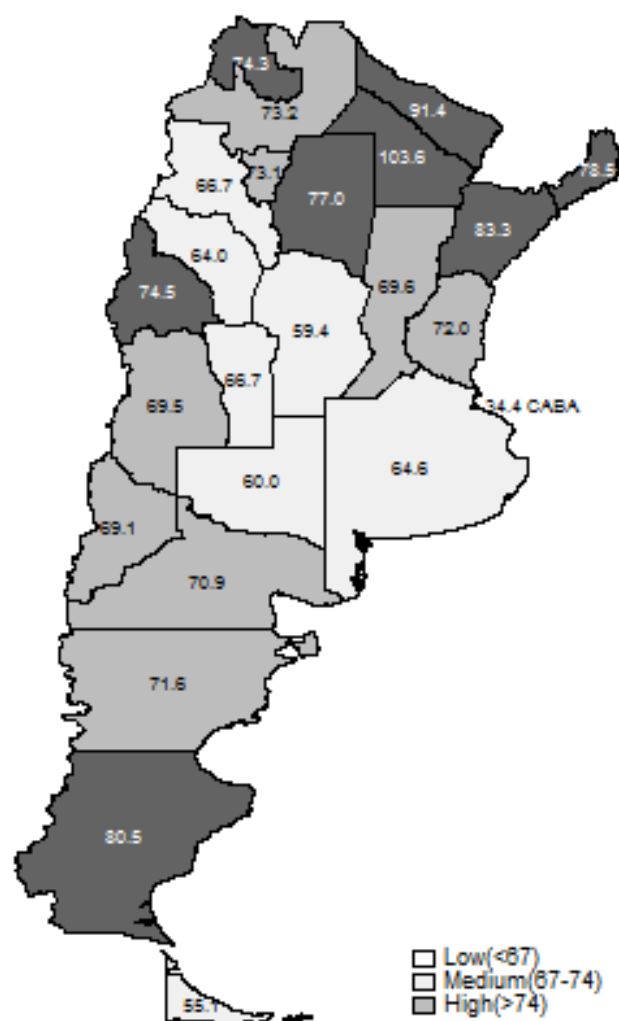

The rest of the paper is organised as follows. Section 2 presents a description of the compulsory schooling changes used for identification, describes the data used in this study, and lays out the methodology. Section 3 presents the main findings and Section 4 concludes.

2. EMPIRICAL STRATEGY

We identify the causal effect of education on fertility by applying an Instrumental Variables approach to deal with the endogeneity of education. Following Black et al. (2008), Silles (2011), Cygan-Rehm and Maeder (2013) and Alzúa et al. (2016), we use an education reform that extended the number of years of compulsory schooling in Argentina (*Ley Federal de Educación*) as an instrument for education. Our identification strategy takes advantage of exogenous variation in education from the staggered implementation of the reform, driven by political reasons uncorrelated with fertility trends.

2.1. The Educational Reform

Ley Federal de Educación (henceforth LFE)⁹ provided the legislative framework which resulted in an increase of the number of years of compulsory schooling in April 1993 from seven to ten in Argentina. It also introduced a significant change in the structure of the educational curricula. Specifically, it replaced seven years of primary school and five years of secondary school with a nine-year uniform cycle called *Educación General Básica* (EGB) and a three-year specialised cycle named *Polimodal*. Pre-primary education for children aged five and EGB were made mandatory. The law applies to both public and private schools in every province. Table 2 shows the structure of the educational system before and after the reform. Table 2 also shows that change in mandatory schooling affects teenagers aged 14 or less. It reports the age at which young people are supposed to reach each level. However, in Argentina the over-age rates are quite high (18.8% in primary level and 38.1% in secondary education, according to DINIECE 2011).

One of the main goals of the LFE was to reduce the high dropout rate in the initial years of secondary education. Indeed, implementation of the reform increased access to secondary education and reduced dropout and repetition rates (Crosta, 2007). In addition, LFE had other unintended effects: a positive impact on labor outcomes (Alzúa et al., 2015) and a reduction of youth crime (López, 2012).

As preliminary evidence of the effects of LFE reform on education, Figure 4 visually represents the effect that this legislation had on increasing average years of schooling in formal education (Panel A) and school enrollment (Panel B). Enrollment rates responded faster than years of schooling. The average number of years of education

⁹ Law 24195, 14 April 1993.

for youths aged 10–14 years has increased over the decade, from 5.4 years in 1995 to about 5.9 years in 2005. For older teenagers, aged 15–19 years, average years of schooling increased from 9.2 in 1995 to 9.9 in 2005. Enrollment rates for youths aged 10–14 neared 100%, increasing from 96% in 1995 to 98% in 2001. For youths aged 15–19, after LFE school enrollment increased by 13 percentage points, up from the pre-reform level of 63%.

Since 1991, primary and secondary public education are administered and financed at the provincial level (previously secondary schools were in hands of the federal government). It was expected that the implementation of the reform would induce an increasing pressure over educational facilities. Provincial governments required larger budgets for investing in infrastructure and teacher's wages, i.e., provinces required federal government cash transfers. For that reason, provinces were more likely to implement the reform early and massively if its ruling political party was the same as the national ruling party (Alzúa et al., 2015).

The timing and degree of implementation of the law differed substantially across provinces. Between the years 1996 and 2000, Provincial governments triggered the education reform. While in some provinces the reform was quickly and massively implemented, in others the changes were put into practice more gradually, involving a much smaller percentage of schools and students (pilot program). Moreover, in two districts (City of Buenos Aires and Río Negro) some central aspects of the reform were never implemented. Furthermore, reform was applied gradually as cohorts reached the age of EGB3 entry (12 years old). So, it took a considerable time for the *Polimodal* to be implemented (Crosta, 2007). Due to all this, exposure to the reform depended on birth-cohort and province of residence.

2.2. Data

Since exposure to the reform depended on age and province of residence, we construct a yearly panel dataset at birth-cohort/province level for the period 1995-2006. In 2007 a new education reform (Law 26206) aimed to return to the old structure of the educational curricula and raise the compulsory schooling again (from 10 to 13 years); so we decided to exclude this period from the analysis.

We assume most women who got pregnant during school year (March-December) t , will give birth the following year $t+1$. Hence, fertility outcomes such as births reflect choices taken one year before. Birth-cohorts run from 1977 to 1994, but they are included only when they are teenagers (12-18 years old).

Teenage fertility rates are the number of live births¹⁰ per 1,000 girls. We include in the analysis fertility information for girls aged 13-19.¹¹ The number of live births by age and province of residence of the mother was provided by the Office of Health Statistics DEIS. The source for female population is the National Statistics Institute INDEC; data is available by province of residence and five-year age groups (we assigned it into single years of age using Sprague's multipliers; Siegel and Swanson, 2004).

In addition, we use two different measures for education: average years of schooling (as a proxy of human capital effect) and enrollment rates (as a proxy of 'incapacitation' effect). Unfortunately, we cannot capture the other mechanisms we briefly discussed above. Education outcomes by sex, age and province of residence were calculated from Argentina Household Survey EPH using SEDLAC database (CEDLAS and the World Bank). The survey sample includes 15 provinces for the entire period, and 8 provinces since 1998 (see Table 3 for details). Unfortunately, for the period 1995-2006 EPH has no information from the province of Río Negro, where some central aspects of the reform were never implemented.

Two complementary indicators measure the implementation of the reform. First, we use Crosta (2007) as a source for the timing of the reform in provinces and we assigned compulsory attendance laws defining a dummy variable on the basis of province of residence and the year when the girl was 14 years old (see Table 3 and Figure A2 in the Appendix). Second, we consider information from DINIECE (Ministry of Education) for the share of students in *Polimodal* for each province (following López, 2012; and Alzúa et al., 2015). This second indicator is capturing: (i) differences in school construction rates and/or percentage of schools that implemented the reform across provinces; (ii) the fact that the reform was applied gradually as cohorts reached 12 years old (the age of EGB3 entry), and it took them considerable time to reach *Polimodal*. We will

¹⁰ We would like to determine the share of pregnant teenagers (i.e., teenage pregnancy rate), regardless of the pregnancy outcome. However, we only have information for one pregnancy outcome: live births. We will use fertility rates as a proxy of pregnancy rates. The difference between these two variables is explained by stillbirths, spontaneous abortion, and induced abortion.

¹¹ Usually these indicators include women aged 10-19, but the number of mothers younger than 13 years old was very low, even zero for some year/provinces.

interpret the dummy variable as the extensive margin of the reform, and the share of students in *Polimodal* as an indicator of reform's progress and expansion (intensive margin).

Finally, we use indicators of economic cycle (Provincial GDP and unemployment rates) and public policies (public expenditure on education and health, and *Plan Nacer*¹² beneficiaries) as covariates.

In summary, we have an unbalanced panel dataset with 1,764 observations at birth-cohort/province level for the period 1995-2006, with information about fertility of women aged 13-19, education outcomes for women aged 12-18, implementation of the LFE, and other covariates which capture economic activity, unemployment, public expenditure on education and health, and *Plan Nacer* beneficiaries. Table 3 summarises the indicators we will use for our estimations and their sources.

¹² *Plan Nacer* is a targeted public health insurance program available for uninsured women who were pregnant or had recently given birth (up to 45 days post-delivery), and children under 6 years of age. The program began in 2004, and uses results-based payments at the provincial and health facility level. It includes a specific package of services which enrolled individuals receive free of charge. Provinces are paid a capitation fee for enrolling qualified beneficiaries, and health facilities receive fee-for-service payments for providing services.

2.3. Identification strategy

For our identification strategy, the following equations are used:

$$(1) \quad FR_{c,j,t+1} = \beta Educ_{c,j,t} + \gamma X_{j,t} + \mu_{c,j} + \delta_t + \varepsilon_{c,j,t}$$

$$(2) \quad Educ_{c,j,t} = \phi LFE_{c,j,t} + \psi Polimodal_{j,t} + \alpha X_{j,t} + \eta_{c,j} + \lambda_t + v_{c,j,t}$$

$$(3) \quad FR_{c,j,t+1} = \xi LFE_{c,j,t} + \tau Polimodal_{j,t} + \pi X_{j,t} + \rho_{c,j} + \sigma_t + \omega_{c,j,t}$$

Where $FR_{c,j,t+1}$ in Equation 1 is the Fertility Rate in year $t+1$ of teenagers living in province j , belonging to birth-cohort c . $Educ_{c,j,t}$ represents two different measures of teenagers' educational attainment in year t : average years of schooling and enrollment rate. $X_{j,t}$ represents other covariates (economic activity, unemployment, public expenditure on education and health, and *Plan Nacer* beneficiaries); δ_t is a set of dummy variables indicating the year (to control for aggregate shocks); $\mu_{c,j}$ is a set of dummy variables indicating birth-cohort/province fixed effects; and $\varepsilon_{c,j,t}$ standard errors clustered at the birth-cohort/province level to correct for serial correlation problems (following Angrist and Pischke, 2009).

When estimating Equation 1 we should bear in mind that the error term may be correlated with education due to two kinds of endogeneity: selection bias and reverse causality.

Selection bias is related to the fact that education and fertility decisions are both affected by unobservable factors, such as social and cultural norms, religious beliefs, and family background. Usually, these factors are established and shaped during childhood and remain constant over time. A major advantage of panel data is that we can remove any time invariant components, including the unobserved heterogeneity related to norms and religion, by using the within estimator. However, there are other unobservable factors that affect both education and fertility and vary over time. For example, preferences for risky behaviors (during adolescence the predisposition to engage in risky behavior changes) imply both a higher probability of becoming pregnant and higher probability of educational failures.

Reverse causality is related to the fact that reproductive decisions and human capital investment are joint decisions.

Ordinary Least Squares (OLS) estimates of β in Equation 1 which do not account for both endogeneity problems could overstate in absolute value the true effect of schooling on fertility.

In order to solve this problem, we will apply an Instrumental Variables approach (IV), using an instrumental variable that induces exogenous variation in schooling but is uncorrelated with other characteristics which affect teenage childbearing. As mentioned above, we use the 1993 education reform that extended the number of mandatory years of schooling in Argentina (*Ley Federal de Educación, LFE*) as an instrument for schooling (following Black et al., 2008; Silles, 2011; Cygan-Rehm and Maeder, 2013; and Alzúa et al., 2016). In that sense,

the LFE affects the decision to remain and move through the educational system but it should affect fertility decisions only through the educational channel.

To calculate IV estimates we use the method of Two-Stage Least Squares (2SLS). First, we estimate Equation 2 where $LFE_{c,j,t}$ indicates if teenagers living in province j , belonging to birth-cohort c were affected by LFE in year t (extensive margin); and $Polimodal_{j,t}$ indicates the share of students in *Polimodal* in province j , in year t (intensive margin). 2SLS allows us to combine more than one instrument in one indicator; in this case, the number of instruments (two) is bigger than the number of endogenous variables (one), so we estimate an over identified model. The vector of covariates $X_{j,t}$ is exactly the same as in Equation 1; we also include year fixed effects (λ_t) and birth-cohort/province fixed effects ($\eta_{c,j}$). Equation 2 allows us to isolate the exogenous change in education as a response to the reform, obtaining $\widehat{Educ}_{c,j,t}$. In the second stage, we replace $\widehat{Educ}_{c,j,t}$ in Equation 1, obtaining β : the average causal effect of $Educ_{c,j,t}$ on $FR_{c,j,t+1}$ for those women whose educational attainment is changed by the reform.

Equation 3 can be derived by substituting the first-stage equation (Equation 2), into the causal relation of interest (Equation 1), obtaining the reduced-form. The reduced-form regression is important because, as Angrist and Krueger (2001)¹³ note, if you cannot see the causal relation of interest in the reduced form, it is probably not there. We will estimate the within transformation of Equation 3 by OLS.

2.4. Internal Validity

2SLS estimates can be interpreted as causal effects for those individuals whose educational attainment is changed by the reform instruments (named *compliers*),¹⁴ given that four conditions are fulfilled (Imbens and Angrist, 1994):¹⁵

- (i) *Independence*, reform exposure is as good as random, conditional upon the controls included.

¹³ Cited in Angrist and Pischke (2009).

¹⁴ We can divide the population into four subgroups, defined by their reactions to the instrument: those induced by the increased schooling requirements to receive more education (*compliers*); those who will attend school with or without the LFE (*always-takers*); those who will not attend college, even after the law (*never-takers*); and those who reduce their investments in schooling as a result of the LFE (*defiers*).

¹⁵ Cited in Angrist and Pischke (2009).

- (ii) *Exclusion restriction*, the education reform should only affect fertility through its effect on schooling choices.
- (iii) *First-stage*, the reform must, on average, affect educational attainment in order for it to be used as a source of exogenous variation in schooling. It is also important that the effect on educational attainment be quite strong.
- (iv) *Monotonicity*, rules out the existence of individuals that reduce their investments in schooling as a result of the LFE (called *defiers*).

In summary, an instrument, which is as good as randomly assigned, affects the outcome through a single known channel, has a first-stage, and affects the causal channel of interest only in one direction, can be used to estimate the average causal effect for students who were induced by the increased schooling requirements to receive more education (*compliers*). This parameter is called the local average treatment effect (LATE). We will now discuss potential threats to the validity of these four assumptions.

The *Independence* assumption would be challenged if there was a correlation between the implementation (timing or intensity) of the reform and pre-reform teenage fertility rates in the provinces. As already mentioned, implementation of the reform was expected to induce an increasing pressure over educational facilities, i.e., provinces would need resources from the central government. For that reason, provinces were more likely to implement the reform early and massively if their ruling political party was the same as the national ruling party (Alzúa et al., 2015). This suggests that the timing and intensity of the reform both depended on political affinity between central and provincial governments, and were thus not correlated with pre-reform fertility rates. Figure A1 provides some evidence supporting the exogeneity of reform implementation and women's fertility decisions. In most provinces, reforms took place when teenage fertility rates were either decreasing or remaining stagnate, suggesting the timing of the reforms was not driven by fertility trends in particular.

Second, selective regional mobility may constitute a threat to the exogeneity of the instrument (violating *Independence* assumption) if parents of school children would have moved to another province in response to the progress of the reform. Because available data has no retrospective information, our instrument is based on current province of residence and may be therefore partly an outcome of the reform. However, data from the

Argentine Household Survey shows that, in 2000, only 3.5% of women aged 13–19 have moved recently (in the past 5 years) from one city to another (this is an upper bound, because it includes people who move within the same province). This evidence suggests that regional mobility should not be a major concern.

Regarding the *Exclusion restriction*, if the education reform is correlated with changes in school quality, and school quality is an omitted variable in Equation 1, this identification strategy may fail (Holmlund et al., 2011). In order to mitigate this concern we include the public expenditure on education as a covariate. Although it is well-known that public expenditure on education is not a good proxy of school quality, the information available does not allow us to include a better proxy.

The precondition for using the reform as an instrument for schooling is the existence of a strong *First-stage* relationship between LFE and educational attainment, which is verified in section 3.2. Besides, Crosta (2007) and Alzúa et al. (2015) showed evidence for this hypothesis.

Finally, the *Monotonicity assumption* fails if there are individuals who are induced by the increased schooling requirements to drop out of school (*defiers*). This seems counter-intuitive, so it seems plausible to assume there are no *defiers*.

We just discussed the internal validity of the two LFE indicators as instruments for schooling in the fertility model. But one concern remains regarding the predictive value of the LATE in a different context: the external validity. LATE identifies causal effects for students who were induced by the increased schooling requirements to receive more education (*compliers*). In order to make inferences for other populations, we need to assume a constant (homogeneous) causal effect across individuals, which is a quite restrictive assumption. In other words, compulsory schooling laws affect the schooling decisions of a subset of individuals who differ from representative agents; because they would not have otherwise pursued a higher level of education.

3. RESULTS

3.1. The effect of educational reform on fertility

Table 4 reports estimations of the reduced equation (Equation 3) of the effect of educational reform (extensive in column 1, intensive in column 2 and combined in column 3) on the teenage fertility rate. As can be observed, the educational reform had a statistically significant negative extensive effect (LFE) on the teenage fertility rate for all cohorts that were affected: a decline in the annual fertility rate of 7.5 (or 7.6) births per thousand girls aged 13-19. On the other hand, the proportion of students in *Polimodal* (a three-year specialised cycle, after mandatory education, created by the reform) had no statistically significant effect on teenage fertility.

These results are robust to the addition of several covariates, which capture economic activity, unemployment, public expenditure on education and health, and *Plan Nacer* beneficiaries (columns 4 to 6). The LFE coefficient does not change qualitatively, but it is slightly lower, ranging from 7.3 to 7.4. Again, the proportion of students in *Polimodal* showed no statistically significant effect.

Then, reduced form estimates indicate that implementation of educational reform (extensive margin) is relevant to explain teenage fertility decisions, while its progress and expansion is not (intensive margin). The causal relations of interest may be hard to identify using the proportion of students in *Polimodal* as an instrument for schooling. For that reason, we will report just-identified estimates using only the dummy variable that captures the implementation of the reform (LFE).

3.2. The effect of the education reform on education

The reform, in order to be a valid instrument, must have a strong effect on educational attainment. We first investigate this by considering the regression results for Equation 2, which are presented in Tables 5 and 6.

The reform increased education by 0.27 years on average; in particular, it increased women's education by 0.24 years (columns 1 and 2, Panel A, Table 5). These results are robust to the addition of covariates, coefficients do not change qualitatively, but they are slightly larger (columns 3 and 4, Panel A, Table 5). The F-statistic on the excluded instrument (*LFE*) is above the rule of thumb value of 10 in all cases (a first-stage F-statistic less than 10 indicates weak instruments, according to Stock, Wright and Yogo, 2002).¹⁶ However, the partial-R² is extremely low in all cases, that is, the variability of *LFE* explains the variability of years of schooling very little, and this result could lead to imprecise estimates in the second stage.

Results from the over-identified model (Panel B, Table 5) do not differ much from the case in which *LFE* is the only instrument: *LFE* coefficients range from 0.25 to 0.27 additional years of education. However, the proportion of students in *Polimodal* had no statistically significant effect on years of education. The F-statistic is above the informal threshold of 10 in columns 1 and 3, but it is below that threshold for the female population (columns 2 and 4) indicating the presence of weak instruments. However, the null hypothesis that instruments are jointly non-significant in all cases is rejected. Once again, the partial-R² is very low in all cases.

Results for the enrollment rate are presented in Table 6. The reform increased the enrollment rate of teenagers by 2.6 percentage points (p.p.); in particular, it increased women's enrollment rate by 2.9 p.p. (columns 1 and 2, Panel A, Table 6). These results are robust to the addition of covariates, coefficients do not change qualitatively, but they are slightly bigger (columns 3 and 4, Panel A, Table 6). The F-statistic is below 10 (except in column 4), but the null hypothesis is rejected in all cases. The partial-R² is extremely low in all cases, that is, the variability of *LFE* explains the variability of enrollment rates very little.

Results from the over identified model (Panel B, Table 6) do not differ much: *LFE* increased enrollment rates by about 2.6 to 3 p.p. The instrument related to the share of students in *Polimodal* had no statistically significant effect on enrollment rates. Although the F-statistic does not reach the informal threshold of 10 in any case

¹⁶ Cited in Angrist and Pischke (2009).

(indicating the presence of weak instruments), the F-test rejects the null hypothesis in all cases. Finally, the partial-R2 is very low in all cases.

To sum up, first-stage estimates indicate that the reform, in its extensive margin, had a statistically significant positive effect ranging from 0.24 to 0.27 additional years of schooling; and an effect on enrollment rates ranging from 2.6 to 3 p.p. However, the progress and expansion of the reform (intensive margin) had no statistically significant effect on education (neither on average years of schooling nor on enrollment rates). These results are robust to the addition of several covariates (coefficients do not change qualitatively), which capture economic activity, unemployment, public expenditure on education and health, and *Plan Nacer* beneficiaries. The F-test allows us to reject the null hypothesis that instruments are jointly non-significant in all cases. However, the F-statistic is below the rule of thumb value of 10 in some cases (indicating the presence of weak instruments) and the partial-R2 is extremely low in all cases, leading to imprecise estimates in the second stage.

3.3. The effect of education on teenage fertility

One additional year of education reduced the number of births per 1,000 women aged 13-19 by 27.7. If we consider one additional year of education for the female population, the reduction in the number of births is larger: 30.8 (Panel A, Table 7). The results from the over-identified model (Panel B, Table 7) are similar, although coefficients are larger in absolute terms. Including covariates in the regressions reduces the coefficients estimated, but it does not modify the statistical significance or the direction of these effects.

In the over-identified model, the Sargan-Hansen test allows us to analyze whether the results are statistically different when using the *Polimodal*, as compared to results obtained when using LFE as the only instrument. In all cases, the null hypothesis cannot be rejected, providing evidence of the validity of the instruments.

Results for the enrollment rate (Table 8) show that an increase of one p.p. in the enrollment rate reduces the number of births per 1,000 women aged 13-19 by 2.9. If we consider an increase of one p.p. in the female enrollment rate, the reduction in the number of births is smaller: 2.6 (Panel A, Table 8). Once again, results from

the over identified model (Panel B, Table 8) are similar, although coefficients are larger in absolute terms. The Sargan-Hansen test cannot reject the null hypothesis in any case, thus indicating the validity of the instruments.

In summary, results provide evidence for a statistically significant negative impact of education on the fertility decisions of teenagers. This negative effect operates through a human capital effect (one additional year of schooling reduces the teenage fertility rate by roughly 26.9 to 35.5 per thousand points) and a weaker ‘incapacitation’ effect (a rise of one p.p. in enrollment rate reduces teenage fertility rate by roughly 2.4 to 3.3 per thousand points). Education reform LFE reduced repetition rates (Crosta, 2007), this may be explaining the weak ‘incapacitation’ effect. For instance, after an education reform in Malawi the average age of students declined, due to lower rates of grade repetition; and the reduction in the time girls remain in school substantially weakened the ‘incapacitation’ effect (Grant, 2015).

Although the estimated effects are very large, we should remember that LATE identifies causal effects for the group complying with the reform (i.e. young people who did not leave school after seven years because of the reform and, otherwise, would not have pursued a higher level of education). This group is not necessarily representative of the overall population.

4. CONCLUDING REMARKS

This paper provides empirical evidence on the impact of education on teenage fertility for Argentina by applying an Instrumental Variables approach, using the 1993 education reform that increased compulsory schooling from seven to ten years (*Ley Federal de Educación*) as an instrument for education. Our identification strategy takes advantage of an exogenous variation in education generated by the staggered implementation of the reform, which responds to political affinity between central and provincial governments (Alzúa et al., 2015).

The education reform seems to have had a significant and positive effect on educational outcomes. Implementation of the reform generated an increase in years of schooling by 0.24 to 0.27 additional years, and an increase in school enrollment rates by 2.6 to 3 percentage points (extensive margin). However, the reform's progress and expansion showed no impact on the stock of human capital or enrollment (intensive margin).

Results provide evidence of a statistically significant negative impact of education on the fertility decisions of teenagers. This negative effect operates through a human capital channel (one additional year of schooling reduced the teenage fertility rate by roughly 26.9 to 35.5 per thousand points) and a weaker 'incapacitation' effect (an increase of one percentage point in the enrollment rate reduced the teenage fertility rate by roughly 2.4 to 3.3 per thousand points). Education reform LFE reduced repetition rates (Crosta, 2007), this may be explaining the weaker 'incapacitation' effect (similar to the case of Malawi; Grant, 2015).

Although the estimated effects are very large, we should interpret the results as the local average treatment effect (LATE) for the group complying with the reform (i.e. for young people who did not leave school after seven years because of the reform). This group is not necessarily representative of the overall population.

Reducing early motherhood is a major policy concern due to its adverse consequences on the child and the mother's health, on socioeconomic variables (intra and inter-generational) and for its public cost. There is evidence that education plays a significant role in fertility decision-making processes among teenagers (Duflo et al., 2015; Black et al., 2008; Baird et al., 2011; Cortés et al., 2010 and 2016; Berthelon and Kruger, 2011; Silles, 2011; Cygan-Rehm and Maeder, 2013; and Novella and Ripani, 2015). This research contributes to the literature for the case of Argentina, where investing in education may be a powerful tool to reduce teenage fertility.
